ABSTRACT

This paper proposes a new vehicle stability control method that quantifies and uses the level of lateral force saturation on each axle/wheel of a vehicle. The magnitude of the saturation, which can be interpreted as a slip-angle deficiency, is determined from on-line estimated nonlinear tire lateral forces and their linear projections that use estimates of the cornering stiffness. Once known, the saturation levels are employed in a saturation balancing control structure that biases the drive torque to either the front or rear axles/wheels with the goal of minimizing excessive under- or over-steer, thereby stabilizing the vehicle. The method is particularly suited for a vehicle with an independent wheel drive system. Furthermore, the method can be used in conjunction with a direct yaw-moment controller to obtain enhanced stability and responsiveness. The benefits of the proposed approach are demonstrated considering a nominally unstable, high c. g. heavy military vehicle in an extreme obstacle-avoidance type maneuver.

1. INTRODUCTION

Vehicle stability control (VSC) systems help reduce accidents by minimizing driver's loss of control of the vehicle during emergency/aggressive maneuvers. Most VSC (also referred to as vehicle dynamics control (VDC)) systems available on the market today are brake-based which mainly extend the functionality of mature hardware technology available for anti-lock braking systems. They facilitate differential (left-to-right) braking to generate the required corrective or stabilizing yaw moment [1, 2, 3, 4]. However, this strategy slows the vehicle against driver intent, leading to wasted energy through heat and contributing to accelerated wear of the friction brakes. An alternative approach for generating the

corrective yaw moment that avoids the drawbacks of brake-based strategies is to distribute the tractive/braking force differentially between driving wheels [5, 6, 7, 8]. Current solutions based on this strategy include the so-called torque-vectoring systems which employ active differentials within conventional power trains [9, 10].

In this paper, the focus is on outlining a new stability control method suitable for vehicles with independent drive systems that act on each wheel (or axle) of the vehicle. Such drive systems can be configured in series electric hybrids, pure electric, fuel cell powered and hydraulic hybrid vehicles. These systems allow stability control functions wherein the traction/braking force of each wheel is manipulated via the torque output of the individual wheel drive units (motors).

For vehicles with independent drive systems, several direct yaw-moment controllers (yaw rate feedback, lateral acceleration feedback or combined feedback), and torque distribution strategies have been previously assessed for some strengths and weaknesses in [7, 11]. These approaches are rather simplistic in that the stabilizing yaw moments were distributed to the individual wheels largely based on pre-determined rules. In this paper, a method is outlined for biasing the front-to-rear torque distribution based on online estimation of the level of saturation on each axle. A feedback controller is setup to reduce the imbalance in the level of saturation between the front and rear axles and thereby stabilize the vehicle. For enhanced performance, this controller can also be combined with a direct yaw-moment controller that solely distributes torque side-to-side.

The rest of this paper is organized as follows. The requisite system modeling is briefly outlined in Section 2. Section 3 outlines the vehicle stability control and details the proposed

method. Section 4 presents demonstrative results for an aggressive maneuver considering an otherwise unstable vehicle. Finally, section 5 presents the conclusions of the work.

2. SYSTEM MODELING

A 7-DOF model is used to represent the handling dynamics for the developed control system. The model includes the degrees of freedom of lateral and longitudinal motions, yaw rotation, and the rotations of the four tires. This model ignores suspension effects and therefore does not consider the pitch, heave, and roll of the vehicle body. Detailed derivations and discussions of the model are given in [7, 8, 12]. The longitudinal, lateral, and yaw equations of motion are:

$$m(\dot{V}_x - V_y \dot{\psi}) = \sum F_x = (F_{xLF} + F_{xRF}) \cos(\delta) - (F_{yLF} + F_{yRF}) \sin(\delta) + F_{xLR} + F_{xRR} - \frac{1}{2} \rho C_D A V_x^2 - mg C_{rr} \quad (1)$$

$$m(\dot{V}_y + V_x \dot{\psi}) = \sum F_y = (F_{yLF} + F_{yRF}) \cos(\delta) + (F_{xLF} + F_{xRF}) \sin(\delta) + F_{yLR} + F_{yRR} \quad (2)$$

$$I_{zz} \ddot{\psi} = \sum M_z = l_f [(F_{yLF} + F_{yRF}) \cos(\delta) + (F_{xLF} + F_{xRF}) \sin(\delta)] + \frac{d_f}{2} [(F_{xRF} + F_{xLF}) \cos(\delta) + (F_{yLF} - F_{yRF}) \sin(\delta)] + l_r (F_{yLR} + F_{yRR}) + \frac{d_r}{2} (F_{xRR} - F_{xLR}) \quad (3)$$

The notations used in (1, 2, 3) are defined in Figure 1.

Figure 1. Schematic of Vehicle Dynamics Model

The tire/wheel dynamics connect the wheel torque to the dynamics of the vehicle via the longitudinal tire forces. The tire/wheel dynamics are given by:

$$I_w \dot{\omega}_i = T_{w,i} - F_{x,i} R_w \quad (4)$$

where i represents left front, right front, left rear, and right rear tires.

Each wheel torque is determined from a vehicle speed controller (or driver model) and/or the vehicle stability controller described in the next section. Ideally, the wheel torques, T_w , will be achieved through driving and primarily regenerative braking, however, friction-based braking will be used as a supplement when regenerative braking alone cannot give the desired level of deceleration.

The tire forces are determined by the operating conditions for each tire, specifically, normal loads, longitudinal slip ratios, and lateral slip angles. Considering the load transfers that occur due to lateral and longitudinal accelerations and differences in the front and rear roll-stiffness distributions, the prevailing tire normal loads can be computed within the simplified 7 DOF model described above. The loads for the left front and left rear tires are given by (others follow similarly):

$$F_{zLF} = \frac{mgl_r}{2L} - A_x \left(\frac{mh_{cg}}{2L} \right) - A_y \left(\frac{ml_r h_{rcF}}{Ld_f} + \frac{m(h_{cg} - h_{rcF})K_{\phi F}}{d_f (K_{\phi F} + K_{\phi R} - mg(h_{cg} - h_{rcF}))} \right)$$

$$F_{zLR} = \frac{mgl_f}{2L} + A_x \left(\frac{mh_{cg}}{2L} \right) - A_y \left(\frac{ml_f h_{rcR}}{Ld_r} + \frac{m(h_{cg} - h_{rcR})K_{\phi R}}{d_r (K_{\phi F} + K_{\phi R} - mg(h_{cg} - h_{rcR}))} \right)$$

(5)

The tire slip ratios and slip angles are computed from the vehicle's longitudinal and lateral velocities, yaw rate, wheel spin and steer angle as:

$$\kappa_i = \frac{\omega_i R_w}{V_{xi}} - 1$$

(6)

$$\alpha_{LF} = \tan^{-1} \left(\frac{V_y + l_f \dot{\psi}}{V_x + \frac{d_f}{2} \dot{\psi}} \right) - \delta \quad \text{and} \quad \alpha_{LR} = \tan^{-1} \left(\frac{V_y - l_r \dot{\psi}}{V_x + \frac{d_r}{2} \dot{\psi}} \right)$$

(7)

Since longitudinal tractive forces of each wheel are to be exploited to influence the lateral handling dynamics, a proper tire model that considers combined slip conditions (longitudinal and lateral) must be used, i.e. models that give $F_x = F_x(\kappa, \alpha, F_z)$ and $F_y = F_y(\kappa, \alpha, F_z)$ are needed. In combined slip conditions, when the longitudinal slip ratio approaches its extreme values ($\kappa = -1$ or ∞) there is no lateral force capacity. Conversely, when the lateral slip angle becomes extreme, the longitudinal force capacity reduces to small values. In the present work, combined slip tire data provided in [13] are suitably scaled and implemented as a multi-dimensional lookup table.

3. STABILITY CONTROL METHOD

3.1. ESTIMATION OF AXLE SATURATION

To achieve vehicle stability, the net torque may be divided between the front and rear axles in such a way as to balance axle lateral force capacity. In order to accomplish, a method is needed to determine the axle lateral force capacity and therefore the level of axle saturation from available vehicle

dynamics sensors. This can be accomplished by estimating the lateral tire forces and estimating axle slip angles.

The front and rear lateral forces can be determined by the inverse of a two degree of freedom handling model given the measured lateral acceleration, yaw rate, steering angle, and estimated longitudinal tire forces. This approach has been derived in previous papers [2, 14] and defines the axle forces as:

$$\begin{Bmatrix} F_{yF,est} \\ F_{yR,est} \end{Bmatrix} = \begin{bmatrix} \cos \delta & \cos \delta \\ a & -b \end{bmatrix}^{-1} \left\{ \begin{bmatrix} mA_y \\ I_{zz} \frac{d\dot{\psi}}{dt} \end{bmatrix} - M_x \right\}$$

(8)

where,

$$M_x = \begin{bmatrix} \sin \delta & \sin \delta & 0 & 0 \\ a \sin \delta - \frac{d_f}{2} \cos \delta & a \sin \delta + \frac{d_f}{2} \cos \delta & -\frac{d_r}{2} & \frac{d_r}{2} \end{bmatrix} \begin{bmatrix} F_{xLF,est} \\ F_{xRF,est} \\ F_{xLR,est} \\ F_{xRR,est} \end{bmatrix}$$

Longitudinal tire forces that are corrected for wheel rotational inertia can be estimated from the controlled torque and speed sensors for each wheel as [2, 4]:

$$F_{xi,est} = T_i - I_w \frac{d\omega_i}{dt}$$

(9)

The axle slip angles are determined through a simple observer to estimate lateral velocity from the sensors of lateral acceleration, longitudinal velocity, and yaw rate:

$$V_{y,est} = \int (A_y - \dot{\psi} V_x) dt$$

(10)

Then the slip angles can be defined by:

$$\alpha_{F,est} = \tan^{-1} \left(\frac{V_{y,est} + a \dot{\psi}}{V_x} \right) - \delta$$

(11)

$$\alpha_{R,est} = \tan^{-1} \left(\frac{V_{y,est} - b \dot{\psi}}{V_x} \right)$$

(12)

Once the axle lateral forces and slip angles are known, the level of saturation of the axle, C_{sat} , can be considered as the

Figure 2. Axle Force Saturation

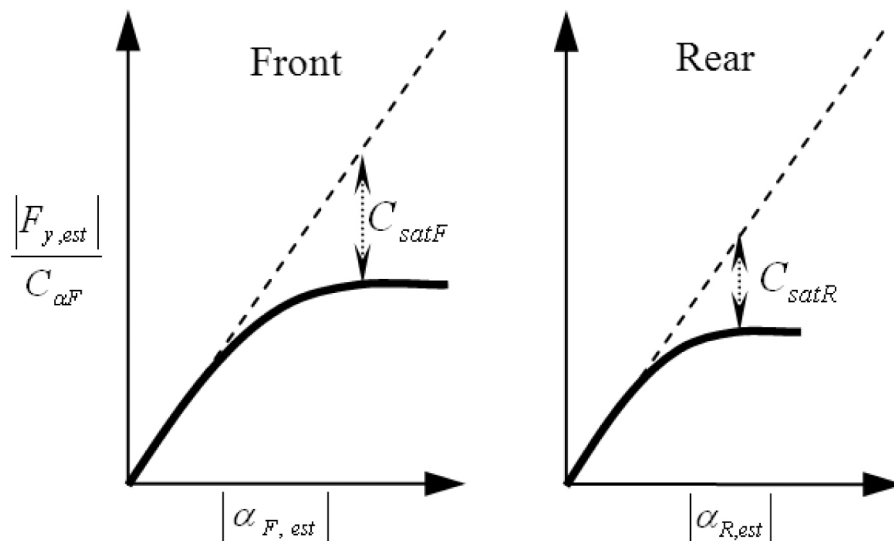

Figure 3. Under Steering Vehicle Axle Force Saturation

deviation from an linear response (using the usual notion of cornering stiffness) as shown in [Figure 2](#).

Assuming that the axle cornering stiffness is a constant, we define the level of axle saturation by:

$$C_{sat} = \frac{F_{y,est}}{C_{\alpha}} - \alpha_{est} \quad (13)$$

The axle saturation defined by (13) can be interpreted as a slip angle deficiency for that axle. It is important to note that the saturation of the front and rear axles occur at different rates and magnitudes. For example, when the front axle saturation is larger than the rear axle saturation ($C_{satF} > C_{satR}$) the vehicle experiences understeer. This scenario is highlighted in [Figure 3](#). Conversely, an oversteering vehicle

can be observed when rear axle saturates more than the front ($C_{satF} < C_{satR}$).

Ideally, a situation of equal saturation levels for front and rear axles avoids excessive under or over-steer for the vehicle. This motivates the possibility of using the estimated axle saturation level directly in the feedback control of vehicle stability.

3.2. SATURATION BALANCING CONTROL

It is widely known that applying tractive force on a front wheel or rear wheel on a vehicle promotes, respectively, understeer or oversteer behavior for the vehicle. Therefore, with this in mind a torque biasing PI control may be defined incorporating the front and rear axle saturations as follows:

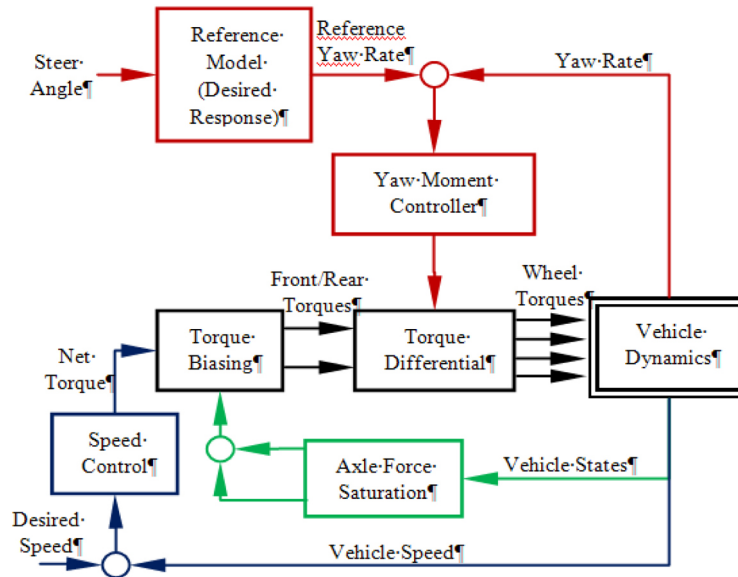

Figure 4. Schematic of Stability Control Architecture

$$\lambda = \left(K_p + \frac{K_I}{s} \right) (C_{satF} - C_{satR}) + \lambda_0 \quad (14)$$

where λ is the percent of net torque to the front axle (limited within the range of 0 and 100%) and λ_0 is the initial torque bias for which no control is required. The front and rear axle torques are then given by:

$$T_F = \begin{cases} T_{total} & \lambda > 1 \\ T_{total} \times \lambda & 0 < \lambda < 1 \\ 0 & \lambda < 0 \end{cases} \quad (15)$$

$$T_r = \begin{cases} T_{total} & \lambda < 0 \\ T_{total} \times (1 - \lambda) & 0 < \lambda < 1 \\ 0 & \lambda > 1 \end{cases} \quad (16)$$

As will be shown distributing torque, front and rear, according to this saturation balancing scheme can provide a level of stabilizing effect on the directional stability of the vehicle.

3.3. COMBINING WITH DIRECT YAW-MOMENT CONTROL

A direct yaw-moment stability controller (of a PID type, as in [1, 3, 7, 11]) is also considered for comparison and for

augmenting the saturation balancing strategy described above. It compares the desired yaw rate to the actual yaw rate of the vehicle to determine if the vehicle has excessive or insufficient yaw rate (traditional indicator of oversteer or understeer). This direct yaw moment controller applies the corrective yaw moment:

$$M_\psi = \left(K_p + \frac{K_I}{s} + K_D s \right) (\psi_{desired} - \psi) \quad (17)$$

where, commonly, $\psi_{desired} = \frac{V_x \delta}{L + (K_{us} V_x^2)/g}$, i.e., the steady state yaw rate response to a steering angle input at the given forward velocity. In this scheme, the yaw moment control is achieved through differential torque variations from left-to-right wheels on the axle with the most lateral force capability as defined by λ from above.

3.4. OVERALL VEHICLE STABILITY CONTROL STRUCTURE

An overall vehicle stability control structure incorporating the above two strategies of axle saturation balancing and direct yaw-moment control is depicted in Figure 4 below.

In the combined scheme, the speed of the vehicle is controlled using a PI controller that computes the base torque required to maintain a desired forward speed. The net torque from the speed controller serves to overcome resistance loads of aerodynamic drag, rolling resistance, and grade. Stability is achieved through the saturation balancing control, which acts to limit excessive under- or over-steer of the vehicle. Finally, the direct yaw-moment control component can be

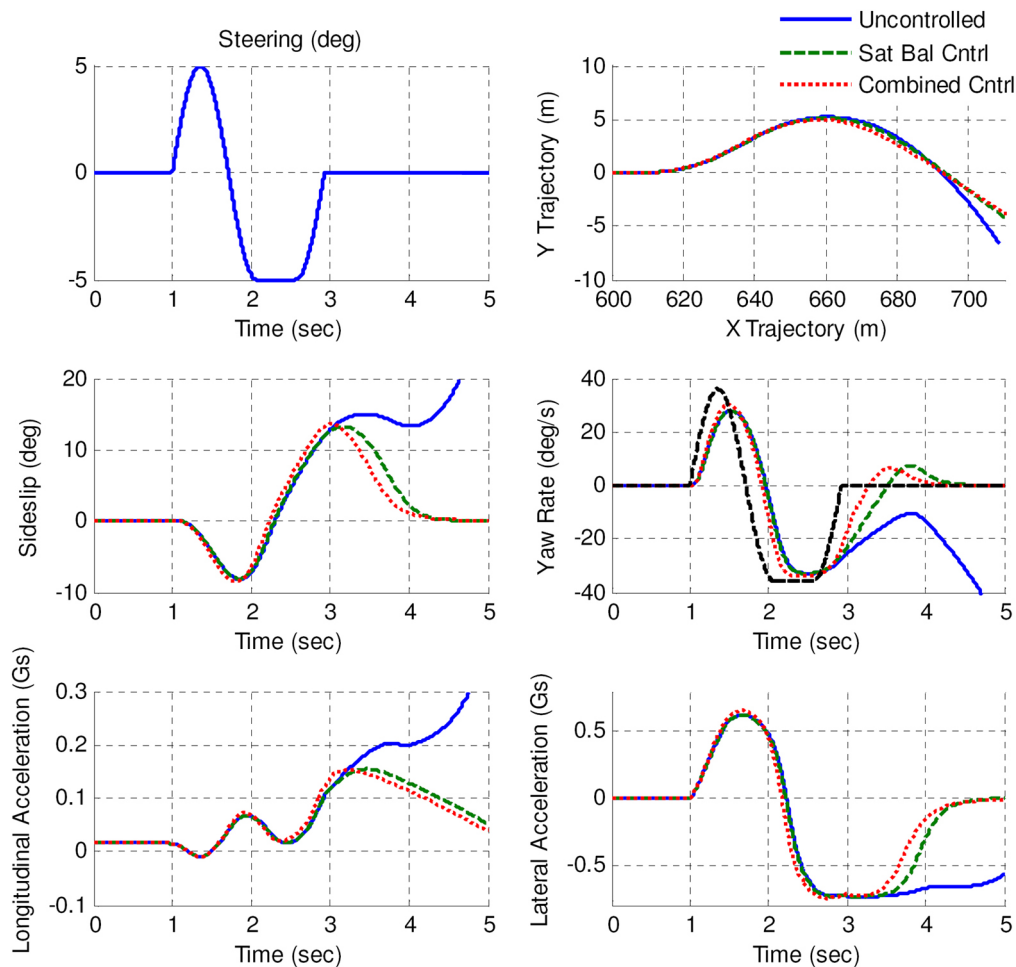

Figure 5. “Sine with Dwell” Vehicle Response for Uncontrolled & Controlled (saturation balancing and combined control) Power Trains

tuned to maintain responsiveness of the vehicle by directing the torques on the left and right wheels of the dominant axle that has the better grip, i.e., the one with the lower level of saturation as identified from the axle force/saturation level estimation.

4. RESULTS AND DISCUSSION

The above stability control methods were applied to a medium duty truck with a GVW of 8000 lbs and with an upgraded power train featuring independent wheel drives. The vehicle considered is a nominally over-steering vehicle (a worst-case scenario) with front-rear distributions of 55%-45% in weight, 40%-60% in initial drive and 40%-60% in roll stiffness, and on dry asphalt road ($\mu=1.0$).

To evaluate the handling performance in aggressive maneuvers, a “sine with dwell” steering angle input was considered. This open-loop maneuver has been defined by NHTSA in the US to emulate a severe obstacle avoidance type maneuver for evaluating VSC systems by inducing a dynamic nonlinear vehicle response [15]. The uncontrolled,

saturation balancing control, and combined stability controlled (saturation balancing and direct yaw-moment control) vehicle responses are shown in [Figure 5](#) for this maneuver at 100 kph.

It can be seen from the figure that the uncontrolled response of the vehicle exhibits unstable over-steer, excessive side-slip angles, and yaw rates. The saturation balancing control does provide stability as expected. The handling response of the vehicle with the combined control (saturation balancing and direct yaw-moment control) shows improvements both in the stability and responsiveness as compared to the uncontrolled response.

To see the internal workings of the saturation balancing control during the maneuver, [Figure 6](#) depicts the level of the front torque bias during the maneuver which is determined by the saturation balancing control.

[Figure 7](#) shows the side-to-side torque differential of the same maneuver which is determined by the direct yaw moment controller.

Figure 6. Front Wheel Torque Bias for Combined Control (within the combined control)

Figure 7. Front Wheel Torque Bias for Combined Control

The direct yaw-moment control is initially dominant in the maneuver due to insufficient yaw response, which can be seen by the side-to-side torque differentiation at time 1-2 seconds (Figure 6). However, the saturation balancing control becomes dominant later in the maneuver to counter impending over-steer seen in the uncontrolled response at time 2-4 seconds (Figure 5).

5. CONCLUSIONS AND FUTURE WORK

This paper discussed the development of a new stability control strategy for a vehicle with an independent-wheel-drive architecture. Axle saturation is explicitly quantified and used in a feedback structure. This was then used along with a

direct yaw-moment control component. The method enabled stabilization of a nominally over-steering vehicle while retaining yaw responsiveness. Simulation results revealed the benefits of each piece of the control scheme: the stable completion of the extreme avoidance maneuver due to the saturation balancing control as well as an improved response from augmenting with direct yaw-moment control.

Further work on this topic will include using other feedback control schemes for vehicle stability control based-on on-line estimated and explicitly quantified axle saturation levels. This includes predictive/optimal schemes that may improve the performance even better.
