Energy Saving Potentials of Connected and Automated Vehicles

Ardalan Vahidi  Antonio Sciarretta

Abstract—Connected and automated vehicles (CAVs) are marketed for their increased safety, driving comfort, and time saving potential. With much easier access to information, increased processing power, and precision control, they also offer unprecedented opportunities for energy efficient driving. This paper is an attempt to highlight the energy saving potential of connected and automated vehicles based on first principles of motion, optimal control theory, and a review of the vast but scattered eco-driving literature. We explain that connectivity to other vehicles and infrastructure allows better anticipation of upcoming events, such as hills, curves, slow traffic, state of traffic signals, and movement of neighboring vehicles. Automation allows vehicles to adjust their motion more precisely in anticipation of upcoming events, and save energy. Opportunities for cooperative driving could further increase energy efficiency of a group of vehicles by allowing them to move in a coordinated manner. Energy efficient motion of connected and automated vehicles could have a harmonizing effect on mixed traffic, leading to additional energy savings for neighboring vehicles.

I. INTRODUCTION

The shift that we are witnessing toward vehicle connectivity and autonomy is going to be perhaps, the most disruptive since the early days of automobiles and could revolutionize movement of people and goods. According to IHS Automotive, the number of connected cars sold globally will grow more to 152 million across the globe by 2020, a six fold increase with respect to 2015 [1]. Another estimate puts the number of connected vehicles at 250 million vehicles by 2020 [2], a fourth of the billion cars that are in service today. In 2016 the US Department of Transportation issued a notice of proposed rule making, that if implemented would require Vehicle-to-Vehicle (V2V) connectivity on all new light-duty vehicles and is intended to reduce the number of car accidents [3]. Similar provisions and guidelines are envisioned for Vehicle-to-Infrastructure (V2I) communication [4]. With implementation of such mandates the number of connected cars with access to information and data will rapidly increase. On a different front, major auto manufacturers, technology firms, and startup companies have started a race toward building fully automated cars. Many automated functions such as adaptive cruise control and lane keeping assist are already available on several production vehicles. It is expected that first fully automated vehicles be available for sale before 2020 [5], [6]. A projection is that 20-40% of vehicle sales be automated by 2030 and full penetration could happen in several stages over the next few decades [7].

This level of connectivity and autonomy will transform transportation of people and goods in several dimensions with important societal and economical impacts: improved safety, increased comfort, time saving potential, and more efficient road utilization are among the most widely discussed positive impacts of CAVs. Fully automated vehicles could improve mobility of young, elderly, and people with disability who are unable to drive today. Ride sharing and on-demand mobility services could gain more popularity due to reduced labor cost, influencing also urban planning and land use.

Energy use has not been the core consideration in development of connected and automated vehicles, but it could be impacted significantly. The impact could be positive or negative according to [8], [9] which is summarized in Table I. A careful scenario analysis in [9] shows vehicle automation could reduce energy use and greenhouse gas emissions in half in an optimistic scenario or double them in a “dystopian nightmare”, depending on the effects that come to dominate. Increased opportunities for eco-driving and platooning, traffic harmonization, vehicle light-weighting enabled by lower crash risk, vehicle right-sizing for number of travelers, de-emphasized vehicle performance, car-sharing and on-demand mobility, and reduced infrastructure footprint of automated vehicles all contribute to improved energy utilization according to [9]. But according to the same study, the increase in vehicle miles traveled due to lower travel costs, addition of new user groups (young, elderly, disabled), higher highway speeds, and increased vehicle features can also dramatically increase the energy footprint of vehicle automation. The outcomes depend on which scenarios prevail and proactive policy making is essential to steer the technology toward energy efficiency as also emphasized in [9], [10], [6]. The authors of [11] speculate that the aggregate energy and environmental impact of automated and on-demand mobility could be positive; but acknowledge a big shift from historical trends that needs to be carefully watched by policy makers and planners.

This paper takes a more in-depth look at increased opportunities for energy efficient driving with connected and automated vehicles, disregarding second order effects of connectivity and automation, such as increased vehicle miles traveled or reduced vehicle weight. Because CAVs are capable of sensing more accurately, processing more information, and can be more tightly controlled, they benefit more from information offered by connectivity and road preview. With higher penetration rate of CAVs, opportunities increase for vehicle to vehicle communication and cooperative control; which can lead to additional energy efficiency gains. Despite

these prospects, connected and automated vehicle research and development have been mostly on software, sensing, and safety and there are limited results on energy efficiency potentials.

Over the past decade, various research groups have shown the positive influence of telematics, road preview, and connectivity on energy efficiency of conventional and hybrid vehicles through simulation and experimental investigations. For instance, in [12] it is shown that as little as 7 seconds traffic look-ahead capability could have the same energy efficiency benefit as hybridization. Due the complex nature of the problem (different vehicle configurations, variability of scenarios, and sensitivity to choice of algorithms) the reported values for energy efficiency benefits are scattered and a concerted effort is needed to summarize the findings and put them in context. Such a summary not only helps researchers in the field but can inform policy making in regulatory units.

We start by discussing the fundamentals of energy efficient driving based on a first principle energy analysis in Section II. Our reference to eco-driving implies economic and not ecologic driving as they are not necessarily the same; lowering energy use is not equivalent to lowering emissions [13]. As formalized in [14] and [15] many eco-driving problems are optimal control problems; but to keep the paper readable to a more general audience we limit use of theory of optimal control to an appendix. The flow of the rest of the paper is shaped by the authors’ past research on eco-driving and backed by the many papers that have emerged on the topic, mostly over the past decade. This is by no means a comprehensive review of existing literature as a wide range of publications exists. In particular we do not consider the topic of eco-routing that has been discussed in several recent publications, especially that of optimally choosing traffic signals, and microscopic motion of their neighboring vehicles. This allows CAVs to more judiciously choose their velocity and lane to minimize wasteful braking and idling and also enables predictive powertrain control due to increased certainty about future vehicle motion. With increased penetration of CAVs, more opportunities arise for collaborative driving which could further enhance energy efficiency as discussed in Section IV. In particular we discuss platooning, cooperative adaptive cruise control, cooperative lane change and merge, and cooperative intersection control for a CAV fleet. The impact on mixed traffic is discussed briefly in Section IV-D, followed by conclusions in Section V.

II. FUNDAMENTALS OF ENERGY EFFICIENT DRIVING

Energy used by a vehicle depends very much on the way it drives. There is a large body of scientific literature on energy efficient- or eco- driving [20], [14], practical guides on hypermiling [21], and the potential impact on energy use and carbon emissions [22]. Connected and automated vehicles have the potential to excel at efficient driving because of their increased situational awareness and ability to execute more complex maneuvers more precisely. Before discussing specific scenarios where CAVs can save energy, here we take a closer look at fundamentals of energy efficient driving. We will consider only a vehicle’s longitudinal motion governed by Newton’s second law of motion:

\[ m \frac{dv}{dt} = F_w - mg \sin \theta + C_r \rho_v A C D v^2 \] (1)

where \( m \) is mass of the vehicle, including powertrain inertial effects, \( v \) is forward velocity. Here \( F_w \) is chosen to be the sum of tractive or braking force at the wheels, thus decoupling the role of vehicle powertrain in the initial part of this discussion. In the term representing road loads, \( C_r \) is the coefficient of rolling resistance and \( \theta \) is the road slope. In the term representing aerodynamic drag, \( \rho_v \) is air density, \( A \) is vehicle front area, \( C_D \) is aerodynamic drag coefficient.

The instantaneous power needed at the wheel is \( F_w(t)v(t) \). Therefore, the net energy needed at the wheel, \( E_w \), to cover a distance \( s_t \) in \( t_t \) unit of time can then be calculated as:

\[ E_w = \int_0^{t_t} F_w(t)v(t)dt = \int_0^{s_t} F_w(s)ds = \int_0^{s_t} \left( m \frac{dv}{dt} + mg \sin \theta + C_r \rho_v A C D v^2 \right) ds \] (2)

With the reasonable assumption that \( m, g, C_r, \rho_v, \) and \( A \) are constants during a trip, integration yields:

\[ E_w = \frac{1}{2} m(v_f^2 - v_0^2) + mg \Delta h + mgC_r \Delta x + \frac{1}{2} \rho_v A \int_0^{s_t} C_D(s)v^2(s)ds \] (3)

where \( v_0 \) and \( v_f \) are velocities at origin and destination respectively. \( \Delta h \) is total elevation change during the trip, and \( \Delta x \) is the horizontal distance covered. Here we assume the drag coefficient can vary along the road, due to potential for platooning or drafting which could reduce aerodynamic drag.

The first and the second terms in Equation (3) represent the change in kinetic and potential energy respectively and are dictated by initial and terminal conditions, so they do

not offer opportunities for reducing $E_w$. Note that road grade does not appear after integration; however we will explain later that because of constraints on velocity and powertrain output, the elevation profile along a trip can have a significant effect on energy use and prior knowledge of it can help save fuel via better constraint management. The term $mgC_D\Delta x$ represents the irreversible frictional loss and is a function of (horizontal) trip distance and $C_D$. So if there is a choice, one must choose shorter routes with lower $C_D$ (concrete road over sand road) to save energy. With connectivity there may be opportunities to evaluate this term more accurately. The last term, the energy lost to aerodynamic drag, is the only term that can be influenced by the decisions along the route and therefore should be a core consideration in eco-driving.

The energy needed at the wheel can be reduced by joining a tight platoon thus lowering $C_D$. The vehicle velocity plays an important role and obviously lower speeds result in lower losses. With connectivity there may be opportunities to evaluate this term more accurately. When decelerating to a stop ($F_w \approx 0$) allowing the velocity to increase toward the equilibrium imposed by rolling resistance and aerodynamic drag. Unfortunately this is very unsafe and often impractical due to road speed limits and the bounds imposed by preceding vehicles. However if the road profile is known in advance, the vehicle can start coasting early in anticipation of an imminent descent, allowing it to utilize the limited velocity band more effectively. An automated vehicle can execute such a maneuver more precisely than a human driven vehicle as explained in more detail in Section III-A.

When descending down a steep road and in a hypothetical scenario where there are no upper bounds on velocity, it is more energy efficient to coast down the hill ($F_w \approx 0$) allowing the velocity to increase toward the equilibrium imposed by rolling resistance and aerodynamic drag. Unfortunately this is very unsafe and often impractical due to road speed limits and the bounds imposed by preceding vehicles. However if the road profile is known in advance, the vehicle can start coasting early in anticipation of an imminent descent, allowing it to utilize the limited velocity band more effectively. An automated vehicle can execute such a maneuver more precisely than a human driven vehicle as explained in more detail in Section III-A.

The above discussion was focused on increasing “wheel-to-distance” [14] energy efficiency and did not address “tank-to-wheel” energy efficiency which is powertrain dependent. The two problems are not entirely decoupled: for instance we showed that low constant velocities improve “wheel-to-distance” energy efficiency due to lower drag. A gasoline engine on the other hand is not most efficient at low loads seen at low speeds. The engine sweet spot is typically at relatively large engine loads. To strike a balance (running the engine efficiently and maintaining a low average speed), the engine could be periodically turned on at high load and then turn off; in a “pulse-and-glide” strategy. The effectiveness of pulse and glide algorithms is shown analytically in [25], using theory of optimal control in [26], [27], and experimentally in [28] but overall the existing literature presents mixed and sometimes conflicting results. We note that pulse and glide may not be a practical eco-driving strategy because velocity variations are uncomfortable to passengers and disruptive to traffic. Also according to [28] pulse and glide may not be an effective approach in vehicles with automatic transmission due to torque converter losses.

In hybrid vehicles, the battery energy storage buffer allows to (partially) decouple the engine load/speed from the wheel load/speed. Therefore the engine can be run more often near its sweet spot, even at low road loads and speeds. Moreover, regenerative brakes contribute to higher energy efficiency. Nevertheless, because the electromechanical energy conversion is always lossy, eco-driving practices can be beneficial even for hybrid vehicles. For instance using connectivity and road preview allows predictive utilization of the limited battery energy buffer to save energy. A pulse and glide strategy can save fuel in hybrids as well [28] but may be undesirable.

The electric motor in electric vehicles is more efficient at lower torques and therefore the energy-optimal operation strategy, unlike for gasoline vehicles, is not pulse and glide [14], [29]. Analytical solutions based on optimal control theory show that the optimal speed profile for an electric vehicle is a parabolic function of time, quite different from that of gasoline engine vehicles [29]. Here automated driving may provide an advantage in the ability to adhere to more complex
speed profiles for energy saving.

III. ANTICIPATION IN CONNECTED AND AUTOMATED DRIVING

CAVs offer huge potentials for boosting road safety, capacity, and efficiency, because of their ability to process data from many more sources (e.g., V2X fused with on-board sensing) and their ability for more precise positioning and control than human drivers. While similar information can be processed, and provided to connected human-driven vehicles [30] [31] (e.g. as optimal speed/lane advisories), only fully automated vehicles can be made to comply with and reliably follow real-time energy-efficient commands. Even in mixed-traffic that involves other non-automated vehicles, energy-efficient automated vehicles can have a positive impact on the energy efficiency of surrounding traffic as will be illustrated later. Automated cars have the potential to uncover the “driving signature” of their neighboring vehicles and predict their most likely actions. They can also anticipate probable locations of slow-downs by systematic evaluation of historical data. Connectivity between cars and infrastructure can make much more information available to each vehicle and the vehicles can form groups and act cooperatively. All of these advances, when put into an organized framework, can help better anticipation and enable improved traffic flow, increased safety, and reduced energy consumption.

A. Anticipating State of the Road

Prior knowledge of road speed limits, safe speeds on curved roads, and an estimate of average traffic speed allows for more energy efficient velocity transitions in anticipation of the change in velocity constraints. Speed limit is a standard feature on modern onboard navigation units. Road curvature may be extracted from navigation maps to calculate the likely (safe) speed on a curve. Curve speeds can also be crowdsourced from connected vehicle data. Average traffic speeds for upcoming segments of a trip can be queried from a Traffic Management Center (TMC) that operate based on local sensors and cameras or estimated from traffic feeds that mostly rely on crowdsourced information, such as feeds of Google, Here, Waze, and Inrix as of 2017. Dynamic spatiotemporal evolution of traffic speed can be estimated via a faster-than-real-time traffic simulation model which is initialized by current traffic speed, deterministically [32] or probabilistically [33]. In absence of real-time traffic information services, time- and location-specific historical traffic data can be used as a baseline predictor [34]. Traffic speed can be imposed as a spatio-temporally varying upper bound on the CAV speed [32]. Speed limit, curve and traffic speeds can be unified [35] into a single spatiotemporal bound on CAV velocity and used not only to optimize velocity transitions of a CAV but also inform its predictive powertrain control functions.

Another dominating factor in vehicle power demand is road grade, in particular on steep roads, and more so for heavier vehicles. While road grade does not explicitly impact \( E_w \) as shown in Equation (3), it influences velocity and torque constraints and gear selection. Therefore advanced knowledge of the road grade, obtained from 3D maps, is very beneficial in predictive powertrain control as shown for instance in [36], [37]. Additionally, due to constraints on velocity, prior knowledge of road grade will allow more judicious use of available velocity band and gear selection [38], [39], [40], [41], [42], [43], [44]; for instance a vehicle can slow down in anticipation of a steep descent or speed up in preparation for a climb. The optimal solution can be non-trivial as shown for a heavy duty vehicle in [45]. Daimler already has a predictive cruise control function in production that adjust a heavy duty truck speed [46] and gear [47] in anticipation of upcoming road grade to increase its energy efficiency by 3% on a highway. This level of achievable improvement is consistent with results in literature as summarized in Table II. Predicted velocity transitions and road grade can reduce energy use also via predictive power split in hybrid powertrains [48], fuel cut-off [49] and cylinder deactivation [50] in combustion engines, and thermal load management [51]. While such predictive powertrain control functions can be exercised in conventionally driven vehicles and some have been extensively studied, they will have a larger impact in CAVs. Real-time access to information due to connectivity and absence of a human driver in a CAV increases certainty of predictions and therefore effectiveness of predictive powertrain control.

\(^\dagger\): Simulation \(^\dagger\): Experimental

B. Anticipating Signal Phase and Timing

When driving on arterial roads, repetitive stops at traffic signals results in loss of energy due to braking and idling, engine and brake wear, and can be uncomfortable and frustrating for passengers. Some of these stops are unnecessary, in particular under light to medium traffic conditions, and are due to lack of information about the state of traffic lights. In
an ideal connected urban area with Vehicle-to-Infrastructure (V2I) connectivity, Signal Phase and Timing (SPaT) can be broadcast to approaching vehicles; so that connected vehicles adjust their speed for a timely arrival at a green light. Vehicle autonomy further facilitates this scenario by taking the burden of speed adjustments away from human drivers.

Eco-driving at signalized intersections and its impact on energy efficiency has been the topic of many papers in recent years. One of the earlier works was presented in [53] and expanded in [54] and showed potential for significant fuel savings in a simulation study. These positive results have been corroborated in [55], [56], [57] and many more publications that have followed them. Experimental results in isolated environments [58], [59] and in real-world traffic conditions [60], [61], [62] show that considerable fuel saving (5-15%) is possible with human drivers in the loop. Even more energy saving is expected in automated driving (or with automated cruise control) where vehicles can adjust their speeds more precisely and effortlessly.

The technology for transmitting traffic signal information to subscribing vehicles has been demonstrated in several research projects [63], [58] and [62]. The SPaT information may be directly transmitted to vehicles within range using Dedicated Short Range Communications (DSRC) technology [61] or may become available by the traffic control center via cellular networks as shown in [62]. A software architecture for cellular communication of SPaT from a server to subscribing connected vehicles is described in [62]. Alternative means of inferring SPaT information via on-board cameras [63] and via crowd-sourcing [64], [65] have also been proposed. Connected Signals [66] is a company in Oregon, USA that has been attempting to build a SPaT information repository one city at a time and provides speed advisory to human drivers via a mobile app [67]. However a much needed real-time server that covers large urban areas is still missing. In absence of real-time SPaT information, it is still possible to use history of observation during daily commutes and to estimate the probability of a green or red over a future horizon, conditioned on the current color of the light [57]. Even when SPaT is available in real-time; the future color of the light is not known with certainty, for instance when the light is actuated by the state of loop detectors. In such a scenario one can still use historical trends, to predict the probability of a red or green over a future time horizon [68].

While simple logical rules, such as those in [53], can be effectively used when approaching a single traffic signal, optimizing the trajectory for a sequence of traffic lights can benefit from more formal methods. The velocity planning problem can be formulated as an optimal control problem where the goal could be minimizing or reducing energy consumption subject to the constraint imposed by red signals. Analytical solution, obtained using Pontryagin Minimum Principle, indicate that fuel optimal solution for a conventional vehicle is not intuitive and requires switching between maximum engine torque (pulse) and engine shut-down (glide) and could include a period of constant speed (cruise) [71], [72]. Obviously the resulting speed profile, while fuel optimal, is uncomfortable to drivers and may also be disruptive to surrounding traffic. Therefore alternative cost functions can be used that take into account passenger comfort; for instance penalizing a weighted sum of travel time and acceleration results in smoother trajectories and less braking, thus saving fuel. Optimizing for multiple lights ahead requires numerical solution methods; in [73] and [57], Dynamic Programming (DP) is utilized to solve the optimal control problem. In [57] lack of deterministic information about the color of the light is handled by including probability of a green in the DP cost function and encourages vehicles to target probable green windows. Receding horizon optimization (model predictive control) has been used in [54] and [74] and to obtain near optimal trajectories at signalized intersections. In [75] the queue is considered when calculating the optimal speed. Eco departure of geared vehicles at traffic signals is discussed in [76]. In [77] speed advisory is proposed in conjunction with signal offsets control (green waving) for arterial bandwidth maximization and energy consumption reduction.

“Selfish” optimization that focuses on eco-driving of a single vehicle could be disruptive to the flow of following vehicles. In [83], while still a vehicle centric optimization is solved, a more “considerate” cost function takes into account the preceding as well as the interest of the following vehicle. More specifically a “safety” term is introduced in the cost function of the host vehicle that penalizes sudden slow downs with respect to the velocity of the following vehicle.

Because this technology is unlikely to be implemented in every vehicle in the near future, it is important to evaluate the influence of equipped vehicles on other vehicles in mixed traffic flow. It is currently prohibitively difficult to do field experiments of a large number of CAVs in mixed traffic. Therefore traffic simulation tools have been used in most studies. The impact of traffic signal advisory on mixed traffic is studied, via microsimulations, in [81], [82], [72]. In [82] and in [81] the authors evaluate the influence of eco-driving or eco-speed control on the immediate neighboring vehicles. In [72] the impact of CAVs on mixed traffic near signalized intersections is studied in traffic microsimulations. The CAVs receive the timing of signals in advance and adjust their speed for a timely arrival at green. It is shown that CAVs not only improve their energy efficiency but as their penetration increases they reduce the energy consumption of conventional vehicles as well. With the increment of CAVs, other conventional vehicles are more likely to follow a smoother moving CAV. By their simple car following strategy, such conventional vehicles may reduce the chance of stopping at intersections as well.

Potential impact on energy efficiency is summarized in Table III.

C. Anticipative Car Following

Human drivers are often reactive when following other cars as their view is often blocked by the preceding car and therefore their event horizon is very limited. In sudden slowdowns, they often fail to consider the vehicles approaching

1The solution for hybrid and electric cars [69] is different and could be more complex
from behind. This is not only disruptive to traffic flow and is unsafe, but it can result in inefficient slow-down of multiple vehicles. Balancing the position dynamically with respect to the preceding vehicle which is typically unknown. Therefore we assume that acceleration of the preceding vehicle decays over the horizon assuming that it travels with constant speed [97]. The position of the preceding vehicle can be projected over the horizon depending on the position of the front and back is cognitively demanding for vehicles. Balancing the position dynamically with respect to the preceding vehicle which induces reactive transitions by the host vehicles. In this context and in the broader context of driver modeling different modeling approaches have been discussed in Sections III-A and III-B one can construct a model to historical data to predict the motion of preceding vehicles. The main challenge that arises here is reliance on the position of the preceding vehicle which is typically unknown. Therefore safety can be guaranteed by enforcing a speed dependent lower bound on inter-vehicle gap over the horizon [94]. Terminal constraints can also be enforced to prevent myopic decisions [95], [96]. The main challenge that arises here is the dependence of the inter-vehicle constraint on the position of the preceding vehicle which is typically unknown. Therefore despite a relatively simple control problem formulation, we may be best to penalize acceleration and deceleration or use of brakes. Safety can be guaranteed by enforcing a speed dependent lower bound on inter-vehicle gap over the horizon [94]. Terminal constraints can also be enforced to prevent myopic decisions [95], [96]. The main challenge that arises here is the dependence of the inter-vehicle constraint on the position of the preceding vehicle which is typically unknown. Therefore despite a relatively simple control problem formulation, we are faced with a difficult prediction problem.

In absence of any information and when only instantaneous velocity or acceleration of the preceding vehicle is known, the position of the preceding vehicle can be projected over the horizon assuming that it travels with constant speed [97] or constant acceleration [29]. Or perhaps it is reasonable to assume that acceleration of the preceding vehicle decays over the horizon to zero with some time constant [35]. When information from the road and infrastructure is available as discussed in Sections III-A and III-B one can construct a deterministic profile that the preceding vehicle is expected to follow.

But often the main source of uncertainty is driving style of the preceding vehicle which induces reactive transitions by the host vehicles. In this context and in the broader context of driver modeling different modeling approaches have been used. For instance [98] proposes fitting a nonlinear autoregressive model to historical data to predict the motion of preceding vehicles. Additional information of the intent of preceding vehicles via V2V communication can enhance such anticipative car following.

While the main goal should be to robustly maintain a safe following distance to the preceding vehicle (imposed as position constraints); the inter-vehicle gap can be judiciously used as a degree of freedom to filter abrupt slow-downs and application of brakes [88] and improve energy efficiency of the host vehicle. Smoother velocity transitions of the host vehicles are expected to positively influence the motion of upstream traffic, reduce the chance of a phantom jam, caused by small disturbance, [89], [90], [91] and lower fuel used by the entire queue of vehicles as experimentally shown in [92].

Because of shorter relevant time scales in car-following, a moving horizon optimization is a natural choice (as opposed to full trip optimization). One can penalize fuel used over a moving horizon or simplify the cost function by penalizing the vehicle deceleration in order to reduce braking events. For a vehicle with a combustion engine the fuel optimal car following strategy could be pulse and glide as shown in [26], [27], [70]; but a pulse and glide strategy is uncomfortable, and could be disruptive to traffic as alluded to in [93]. Therefore it may be best to penalize acceleration and deceleration or use of brakes. Safety can be guaranteed by enforcing a speed dependent lower bound on inter-vehicle gap over the horizon [94]. Terminal constraints can also be enforced to prevent myopic decisions [95], [96]. The main challenge that arises here is the dependence of the inter-vehicle constraint on the position of the preceding vehicle which is typically unknown. Therefore despite a relatively simple control problem formulation, we are faced with a difficult prediction problem.

In absence of any information and when only instantaneous velocity or acceleration of the preceding vehicle is known, the position of the preceding vehicle can be projected over the horizon assuming that it travels with constant speed [97] or constant acceleration [29]. Or perhaps it is reasonable to assume that acceleration of the preceding vehicle decays over the horizon to zero with some time constant [35]. When information from the road and infrastructure is available as discussed in Sections III-A and III-B one can construct a deterministic profile that the preceding vehicle is expected to follow.

But often the main source of uncertainty is driving style of the preceding vehicle which induces reactive transitions by the host vehicles. In this context and in the broader context of driver modeling different modeling approaches have been used. For instance [98] proposes fitting a nonlinear autoregressive model to historical data to predict the motion of preceding vehicles. Additional information of the intent of preceding vehicles via V2V communication can enhance such anticipative car following.

While the main goal should be to robustly maintain a safe following distance to the preceding vehicle (imposed as position constraints); the inter-vehicle gap can be judiciously used as a degree of freedom to filter abrupt slow-downs and application of brakes [88] and improve energy efficiency of the host vehicle. Smoother velocity transitions of the host vehicles are expected to positively influence the motion of upstream traffic, reduce the chance of a phantom jam, caused by small disturbance, [89], [90], [91] and lower fuel used by the entire queue of vehicles as experimentally shown in [92].

Because of shorter relevant time scales in car-following, a moving horizon optimization is a natural choice (as opposed to full trip optimization). One can penalize fuel used over a moving horizon or simplify the cost function by penalizing the vehicle deceleration in order to reduce braking events. For a vehicle with a combustion engine the fuel optimal car following strategy could be pulse and glide as shown in [26], [27], [70]; but a pulse and glide strategy is uncomfortable, and could be disruptive to traffic as alluded to in [93]. Therefore it may be best to penalize acceleration and deceleration or use of brakes. Safety can be guaranteed by enforcing a speed dependent lower bound on inter-vehicle gap over the horizon [94]. Terminal constraints can also be enforced to prevent myopic decisions [95], [96]. The main challenge that arises here is the dependence of the inter-vehicle constraint on the position of the preceding vehicle which is typically unknown. Therefore despite a relatively simple control problem formulation, we are faced with a difficult prediction problem.

In absence of any information and when only instantaneous velocity or acceleration of the preceding vehicle is known, the position of the preceding vehicle can be projected over the horizon assuming that it travels with constant speed [97] or constant acceleration [29]. Or perhaps it is reasonable to assume that acceleration of the preceding vehicle decays over the horizon to zero with some time constant [35]. When information from the road and infrastructure is available as discussed in Sections III-A and III-B one can construct a deterministic profile that the preceding vehicle is expected to follow.

But often the main source of uncertainty is driving style of the preceding vehicle which induces reactive transitions by the host vehicles. Or perhaps it is reasonable to assume that acceleration of the preceding vehicle decays over the horizon to zero with some time constant [35]. When information from the road and infrastructure is available as discussed in Sections III-A and III-B one can construct a deterministic profile that the preceding vehicle is expected to follow.
vehicle. In [88] the future motion of a group of preceding vehicles is estimated via traffic microsimulations. Many have used Markov chain models to capture the statistics of velocity transitions. In essence, historical driving data from a particular driver is used to count transitions from a certain velocity (acceleration) to another and then calculate the probability of such a transition [99]. One can then sample many potential velocity trajectories with associated probabilities and integrate them to obtain a probability distribution for the position of the preceding vehicle over a prediction horizon [100]. The inter-vehicle gap constraint can be enforced probabilistically (chance constraint) and then converted to a deterministic constraint as shown in [100], [34]. Alternatively one can solve a stochastic moving horizon optimization as shown in [101], [102], [97], [103]. For instance, in [102] the host vehicle speed is adjusted, using Stochastic Model Predictive Control (MPC), based on Markov chain predictions of traffic speed and road grade.

In an ideal scenario when all vehicles communicate, each vehicle can solve its own optimization problem and pass on its intended action to the vehicles that follow it [95], [104]. This allows a host vehicle to know, with more certainty, the position of the preceding vehicle(s) over the optimization horizon and is believed to result in smoother flow and improved overall energy efficiency. Note that in this scenario, the vehicles are just sharing intentions and do not necessarily cooperate toward a common goal. Later in section IV-A we discuss a cooperative cruise control scenario where the vehicles could cooperate toward a “social” optimum.

With a queue of communicating vehicles, this becomes a distributed MPC problem [104] that is solved sequentially from the front to the back of the queue. Alternatively, a centralized optimization problem can be solved on a central server for all participating vehicles and its decisions communicated to each vehicle [105]; however a central coordination scheme is complex to implement, except maybe for freight transport, and is less likely to prevail in the authors’ opinion.

A different approach is proposed in [88] where it is assumed that all vehicles in a queue communicate their immediate state (position, velocity, acceleration) but not their intentions. The host vehicle assumes a standard car following model for the preceding vehicles to anticipate their positions over its optimization horizon. A similar approach is discussed in [106] and [107]. In a less than ideal scenario, when only a portion of the vehicles in a queue communicate, the position of non-communicating vehicles is inferred in [108] at signalized intersections. Communication delay make the problem even more complex and is discussed in [109], [106]. Packet drops resulting in stochastic delays in connected cruise control and the impact on string stability are discussed in [110].

Table IV highlights selected results that show the impact of anticipative car following on energy efficiency. As can be seen the reported gains vary significantly even for vehicles of the same size. This could be due to design and parameters of the car-following algorithms and scenario setups.

D. Anticipative Lane Selection and Merging

Most existing literature on eco-driving assume the vehicle maintains a single lane, reducing optimization of the vehicle motion to the choice of its velocity. In multi-lane roads, the freedom to choose a different lane provides a new dimension and many more possibilities for optimizing the motion (velocity) of the vehicle to safely improve its energy efficiency and even harmonize traffic. But every day driving experience indicates that choice of lane is a complex decision making problem, perhaps due to its combinatorial nature and typical lack of information about the average speed (or efficiency) of adjacent lanes. The same is true when merging into a highway from an on-ramp or exiting to an off-ramp. Lane selection can be a dilemma point for average drivers; aggressive lane change on the other hand can be unsafe and disruptive to the flow and efficiency of upstream traffic. Even “considerate” drivers who merge early, out of an ending lane reduce the road capacity and slow down traffic [112].

In a connected and automated vehicle environment, more information about the intention of neighboring vehicles can become available via V2V communication, speed of each lane could be broadcast from roadside sensors, and therefore automated vehicles can change lanes more judiciously and smoothly. A rather comprehensive survey of lane change/merge for CAVs can be found in [113], [114]. One of the original formulations in this area can be found in [115].
where choice of lane is an additional integer decision variable in the energy cost of the vehicle. Each CAV runs a microsimulation initialized by the current state of neighboring vehicles to determine the traffic scene over its optimization horizon. Lane and velocity of the vehicle are optimized accordingly. A hybrid optimization approach is presented in [117]. A scenario-based model predictive approach in [118] is intended for safe automated lane changing but also benefit energy efficiency.

*S: Simulation *equipped vehicles (all traffic)

Merging from ramps often causes breakdown and a phantom traffic jam in a highway. Today, solutions such as ramp metering are being used to remedy the situation [120], [121] which requires infrastructure investment and maintenance. With CAV technology the merge can be coordinated much more safely as experimentally shown in [122] resulting in smoother traffic [123], [124] and higher energy efficiency [119]. The impact could go beyond individual vehicles; by reducing the chance of a phantom jam, the overall energy efficiency of traffic will improve. Table V the limited results that authors could find on the impact of lane selection on energy efficiency.

**IV. INCREASED OPPORTUNITIES FOR COOPERATIVE DRIVING**

In a connected vehicle world, deliberate exchange of intentions by vehicles and infrastructure reduces the need for guesstimating the surrounding traffic patterns and therefore enables better coordination. Automated vehicles can cooperate rather than compete for right of way in urban areas and highways, thus contributing to harmony in motion and improved mobility and efficiency of a group of vehicles. Therefore “cooperation” in what follows, refers to sharing information and coordinating movements for a “common” goal. Even with the best intentions of human drivers, cooperation among conventional vehicles is rather challenging due to often unknown plan of neighboring vehicles and complexity of coordination at speed. For instance, merging from a ramp into a highway lacks a clear protocol and is often done in “adhoc” manner in the hope that fast approaching vehicles act with “consideration”. This is not only unsafe, but the need for frequent braking in dilemma zones increases energy use and could negatively impact traffic flow. Information sharing via connectivity allows establishing more systematic coordination protocols that increase safety and efficiency. Automated vehicles can be programmed to take full advantage of such protocols that may require precise movement coordination. We describe below cooperation in car following, merging, lane changing, and intersection crossing and also discuss their potential impact on efficiency of cooperating vehicles as well as benefits to mixed traffic.

**A. COOPERATIVE CAR FOLLOWING**

Cooperative car following in which vehicles coordinate in longitudinal formations is perhaps the most researched topic in cooperative driving, under the contexts of platooning and cooperative adaptive cruise control. Tight platooning gained popularity in the 1990s for its potential to increase highway throughput. In a platoon of communicating and partially automated vehicles, the gap between a group following vehicles can be safely reduced to increase road capacity. Moreover at short following distances, the aerodynamic drag coefficient is smaller resulting in significant energy savings, in particular for heavy duty vehicles. Recognized research programs in the USA [125], [126], Europe [127], [128], [129], and Japan [130] have demonstrated the feasibility of the technology in well documented road experiments as discussed in [131] showing potential for 5-15% energy saving. Experimental results in [128], [129] show between 4 to 7 percent energy saving potential for a heavy truck. Over the years, important technical challenges such as platoon string stability [132], communication needs [133], [134], control design [135], [136], and formation scheduling [137] have been addressed. Today the technology has matured to the extent that major manufacturers and startup companies plan on delivering truck platooning solutions to the market in the near future with the goal of reducing energy and personnel cost [138].

Over the past few years and with increased prospects for vehicle connectivity, Cooperative Adaptive Cruise Control (CACC), has gained popularity in the research community. CACC is essentially an enhanced Adaptive Cruise Control (ACC) system that, in addition to range sensor feedback, relies on wireless communication of the acceleration of the preceding vehicle(s) for feedforward control. V2V communication is intended to increase safety and allows string-stable reduction of the inter-vehicle gap for improved road utilization [139]. With a correct design, velocity variations are much better attenuated than in ACC car following, as shown in road experiments with six equipped vehicles in [140]. Experimental results in [141] showed string stable operation of a CACC design at a short time headway of 0.6 seconds in scenarios where a production ACC design failed to maintain stability even though it was operating at larger 1.1 second headway. The 2011 Driving Challenge in Netherlands was a successful showcase of CACC technology by multiple teams. An overview of this competition is presented in [142], [143] and the details of each team’s technical contribution is well documented in separate papers [144], [145], [146], [147], [148], [149]. CACC formations could positively or negatively impact surrounding traffic as demonstrated in a simulation study [150], for instance long formations may prevent those that intend to merge into a highway. But overall, CACC is expected to have a harmonizing
impact on participating vehicles and on surrounding traffic, reducing braking events and lowering energy consumption. Despite these benefits there are few papers documenting the energy efficiency impact of CACC, for instance [98]. It appears that reducing energy efficiency has been mostly the focus of truck platooning projects.

While the platoon and CACC terminologies are sometimes interchangeably used in the literature, there are some differentiating features. The original concept of a platoon relied on a designated lead vehicle and a hierarchical control structure from the lead to the following vehicles. This hierarchy is not needed in CACC car following and each vehicle can individually switch to its CACC mode as long as it receives messages communicated by its preceding vehicles. The information flow between vehicles can vary from one implementation to the other. A vehicle can receive information from the lead vehicle only, from its preceding vehicle only, or from multiple preceding vehicle as schematically shown in [106] and [151]. Depending on the information flow and content shared between vehicles, we can envision enhanced versions of current platooning and CACC practices. Ideally each vehicle will share its intended acceleration profile over a future horizon, rather than its instant acceleration, with all its following vehicles [95], [104]. This reduces the uncertainty about the movement of preceding vehicles as was discussed in Section III-C aiding each vehicle to better plan its motion and reduce braking events. Note that in this scenario, cooperation is only via information sharing, and each vehicle optimizes its “selfish” cost function. In a true collaborative environment, a group of CAVs not only share information but look for the “social optimum” by optimizing a common cost function [104] or by formation consensus rules [152]. The common goal for instance could be reducing the fuel consumption of the entire fleet [105], [153], [83], string stability [154], or collision mitigation [155]. A common cost can still be optimized in a distributed fashion onboard each vehicle based on information communicated by neighboring vehicles to reach a consensus [154], [153]. In a centralized control framework described in [153], the common fuel cost is optimized on a central cloud server for a group of freight trucks and the decision is issued to low-level controllers of individual trucks. Table VI summarizes some of the limited results on energy efficiency impact of cooperative car following, including platooning.

†: Simulation ††: Experimental

Cooperative lane selection and merge not only contributes to efficiency of the cooperating fleet but can also have a positive harmonizing effect on surrounding traffic.

There is a large body of literature on lane change models for traffic microsimulations, such as the widely used MOBIL lane change model introduced in [158]. However cooperative lane selection and merging for CAVs has only been recently discussed. In [159] a cooperative lane-changing algorithm is simulated that considers follower vehicles in current and target lanes when making a lane change decision. The simulations in [159] show improvement with respect to MOBIL, in terms of merge time and rate, wait time, fuel consumption, average velocity, and flow at the cost of slightly increased travel time for main road vehicles. In [160] a merging assistant system that relies on vehicle cooperation, reduces the number of “late-merging” vehicles and subsequent likelihood of flow breakdowns. Different algorithms for cooperative merging have been proposed, for instance [161] proposes a decentralized control method and [157] formulates it in a model predictive control framework. A cooperative V2V “negotiation” process for lane changing is described in [162] and [163] proposes interaction protocols for cooperative lane changing. Experiments with 3 CAVs performing a semi-automated cooperative lane change maneuver are described in [164] and show the potential for smoother velocity trajectories. The focus of the above results has not been energy efficiency and only [159] reports energy efficiency gains. However, we expect considerable energy saving from wide deployment of cooperative lane changing and merging system due to reduced braking events.
and harmonizing effect on traffic flow.

C. Cooperative Intersection Control

The coordination and optimal timing of traffic signals are by nature complex problems and backed by years of research in traffic engineering and operations research. Current signal timings are mostly scheduled offline, the optimized timings are then deployed as fix timetables for different times of the day. Many signals are actuated by traffic and have rules to override their pre-optimized timetables based on the state of their loop-detectors to reduce idling at intersections. While these traffic responsive control strategies calculate their timing in real-time [165], they act based on the immediate state of loop-detectors. On the other hand, smart traffic signal controllers in connected vehicle environments will do more than just signaling right of ways and act intelligently as hubs that sense, route, and harmonize the flow of arterial traffic.

The research on uni-directional signal to vehicle communication for improving efficiency by providing speed advisory to individual vehicles was discussed in Section III-B. Another research direction has focused on improving intersection flow by optimizing timing of traditional traffic signals informed by uni-directional communication from connected vehicles [166], [167]. In addition, bi-directional vehicle-signal communication allows the geographical data of the connected vehicles to be also wirelessly transmitted in real-time to smart traffic signal controllers [168]. This increases energy efficiency and intersection flow as signals adjust their timings and vehicles their speeds [77].

Automated vehicles can further benefit from the communicated traffic signal information because they not only process the incoming information rather effortlessly but also can precisely control their speed and arrival time at a green light. The situation can get even better with 100% penetration of automated vehicles since a physical traffic light is not needed anymore as shown in concept papers by [169], [170], [171]. Also because automated cars have much faster reaction times than human driven vehicles, the intersection controller can rapidly switch between phases [172]. Some of the benefits of eliminating traffic signals in an all automated vehicle environment is discussed in [169] and demonstrated by interesting simulation results in a recent publication [173]. In [174] show the potential for 50% energy efficiency gain via such reservation-based intersection control systems. In recent papers by Fayazi et al. [175] increasing the intersection throughput is formalized as an Mixed Integer Linear Programming optimization problem. They show significant reduction in number of stops and fuel use compared to traditional intersection control schemes. In a one hour microsimulation case study it is shown that the number of stops can be reduced 100 times [176]. Via a vehicle-in-the-loop experiment [177] they measure 20% improvement in energy efficiency of a real-vehicle that interacts with the intersection controller and hundreds of simulated vehicles. The proposed MILP-based controller resides on a computational server and creates a live picture of evolving traffic conditions by tracking all subscribing vehicles. Based on the location and speed of all the vehicles, the controller optimally and regularly schedules the intersection access time for each vehicle. In addition to minimizing intersection delay and ensuring intersection safety, the desired arrival time of the vehicles is incorporated into the optimization problem in such a way that vehicles would not face extreme delay or expedite compared to their desired arrival times. Simulations indicate benefits of such systems greatly increase if vehicles move in platoons, in certain cases doubling the arterial network capacity with the coordination of platoons and intersections [178]. In [179] a platoon-based approach shows up to 20% energy efficiency benefit with respect to signalized intersections, but under simulation conditions of [179] energy efficiency was a little sacrificed to form platoons. Table VII highlights some of the key results on energy benefits of cooperative intersection control.

D. Indirect Benefits Through Traffic Harmonization

Coordinated and smoother motion of CAVs could harmonize the surrounding traffic and contribute to energy efficiency of conventional vehicles, even at low penetration levels. While it is difficult to establish the network wide benefits experimentally, there are microsimulation case studies and isolated experiments that show such positive impacts. For instance in Section III-B we explained that according to [72] traffic signal speed advisory can reduce the energy consumption of conventional vehicles at moderate penetration rates. Several papers have shown the harmonizing effect of automated cruise control on the upstream traffic [88], [182] which is expected to positively influence energy efficiency of upstream traffic. CACC not only increases road utilization due to smaller gaps [150], [139], [183], but is shown to attenuate velocity variations as shown in road experiments in [140], [141]. These findings are corroborated by microsimulation studies, reported in [184], that show reduction of shock waves with increased penetration of connected and automated vehicles. In [185] a “theory for jam-absorption driving” is presented which is a method for driving a single car to attenuate a traffic
V. CONCLUSIONS

This paper presented an overview of energy-efficient driving opportunities provided by connected and automated vehicles through first-principle analysis and a survey of eco-driving literature. Unprecedented access to information via advanced sensors and V2X communication, increased processing power, and precision positioning and control, enables connected and automated vehicles to plan and execute eco-driving maneuvers much better than a human driver. While there are limited previous studies on energy impact of CAVs, review of the eco-driving literature promises considerable benefits. In particular our conservative evaluation based on published experimental results indicates 3% energy saving from preview of static road information such as road grade in highway driving. Information collected by traffic signals via V2I, could lead to 10% energy saving in arterial driving. With full penetration of CAVs reservation based intersections could yield up to 20% savings. Anticipative car following has a more uncertain impact but could at least yield 3% gain or much higher depending on the driving scenario. Platooning for trucks could yield 7-10% gain due to drag reduction. Cooperative car following and lane selection for passenger cars could boost energy efficiency but there is a lack of experimental results to report. And the harmonizing impact of CAVs on traffic, even at low penetration levels, could result in 20% savings in stop and go driving.

Most of the benefits can be achieved without additional hardware costs and relying mainly on software and information. Higher energy efficiency is an attractive added feature of CAVs, beyond safety and comfort, that could accelerate their market adoption. With higher penetration, there will be system wide influences by such “eco-CAVs”, potentially lowering global energy use and contributing positively to the environment. Energy efficient driving of CAVs could be encouraged by proactive policy making countering alternative scenarios in which higher CAV-miles traveled at higher speeds increase global energy use.

APPENDIX

We want to find the velocity profile that minimizes the “wheel-to-distance” energy losses, going from velocity of \( v_0 \) to \( v_f \) over a specified time of \( t_f \) and distance of \( s_f \). Here we break down the wheel force \( F_w \) to tractive force \( F_t \) and braking force \( F_b \). Considering the tractive acceleration, \( u_t = \frac{F_t}{m} \), and braking deceleration \( u_b = \frac{F_b}{m} \) as the two inputs, and choosing position as the independent variable, the equations of motion can be written in the following state-space form:

\[
\begin{align*}
\frac{dt}{ds} &= \frac{1}{v} \\
\frac{dv}{ds} &= \frac{u_t - u_b - \beta v^2 - h(s)}{v}
\end{align*}
\]

where \( \beta = \frac{1}{m}0.5\rho_a C_D \) and \( h(s) = g\sin\theta + C_r\cos\theta \). The boundary conditions are:

\[
v(s_0) = v_0, \quad v(s_f) = v_f, \quad t(s_0) = 0, \quad t(s_f) = t_f
\]

To keep the derivation applicable across a wide range of vehicles, we assume that a fraction \( \eta \) of the braking energy can be recuperated (\( \eta = 0 \) for conventional vehicles and \( \eta = 1 \) for vehicles with ideal regeneration). Therefore to optimize the “wheel-to-distance” energy expenditure, we minimize the following cost function, which is energy spent normalized by vehicle mass:

\[
\min_{u_t,u_b} J = \int_0^{s_f} (u_t - \eta u_b)ds
\]

subject to the equations of motion and their imposed boundary conditions. It is assumed that there are no bounds on the states over the control interval but \( 0 \leq u_t \leq \bar{u}_t \) and \( 0 \leq u_b \leq \bar{u}_b \). Replacing for \( u_t \) from Equation (5), we obtain:

\[
J = \frac{1}{2}(v_f^2 - v_0^2) + \int_0^{s_f} h(s)ds + \int_0^{s_f} (\beta v^2 + (1 - \eta)u_b)ds
\]

The first two terms do not depend on the control input. Therefore we solve the following problem:

\[
\min_{u_t,u_b} \int_0^{s_f} (\beta v^2 + \gamma u_b)ds
\]

where \( \gamma = 1 - \eta \), so in absence of regeneration \( \gamma = 1 \).

Following Pontryagin’s Minimum Principle [188], the Hamiltonian \( \mathcal{H} \) is formed as follows:

\[
\mathcal{H} = \beta v^2 + \gamma u_b + \lambda v + \mu \frac{u_t - u_b - \beta v^2 - h(s)}{v}
\]

where \( \lambda \) and \( \mu \) are the costates with the following dynamics:

\[
\begin{align*}
\frac{d\lambda}{ds} &= -\frac{\partial \mathcal{H}}{\partial v} = 0 \Rightarrow \lambda = \text{constant} \\
\frac{d\mu}{ds} &= -\frac{\partial \mathcal{H}}{\partial \mu} = -2\beta v + \frac{1}{v^2} + \mu \left( \frac{u_t - u_b - h(s)}{v^2} \right) + \beta \mu
\end{align*}
\]

where boundary conditions for both \( \lambda \) and \( \mu \) are free, since both states, \( t \) and \( v \), are fixed at initial and final positions. We also note that \( \lambda \) is a constant over position, since its rate of
change is zero while dynamics of $\mu$ is more complex. The optimal inputs should minimize the Hamiltonian. Since $H$ is an affine function of $u_t$ and $u_b$, and therefore

$$\frac{\partial H}{\partial u_t} = \frac{\mu}{v}, \quad \frac{\partial H}{\partial u_b} = \gamma - \frac{\mu}{v}$$

are independent of the inputs, the Hamiltonian is minimized at extreme values of the inputs, except for when the partial derivative of $H$ with respect to the inputs is zero, in which a so-called singular interval may exist. Over a singular interval the inputs could assume a value within their constraints. The optimal traction force, denoted by $u_t^*$ is:

$$u_t^* = \begin{cases} \ddot{u}_t & \mu/v < 0 \\ u_t^* & \mu/v = 0 \\ 0 & \mu/v > 0 \end{cases}$$ \hspace{1cm} (11)

where $u_t^*$ denotes the wheel traction during a possible singular interval. For a singular interval to exist, the condition $\frac{\mu}{v} = 0$ must be valid for a position interval rather than just at one point. Therefore over a singular interval we must have

$$\frac{d}{ds} \left( \frac{\mu}{v} \right) = \frac{1}{v} \frac{d\mu}{ds} - \frac{\mu}{v^2} \frac{dv}{ds} = 0$$ \hspace{1cm} (12)

upon substitution from (5) and (10), the condition for existence of a singular interval simplifies to:

$$\frac{d}{ds} \left( \frac{\mu}{v} \right) = -2\beta + \frac{\lambda}{v^2} + \beta \frac{\mu}{v} = 0$$ \hspace{1cm} (13)

but since on a singular interval during traction $\frac{\mu}{v} = 0$, we conclude:

$$v_t = \left( \frac{\lambda}{2\beta} \right)^{\frac{1}{2}}$$ \hspace{1cm} (14)

which is a constant since optimal $\lambda$ was shown to be a constant. As a result the traction force is $u_t^* = \beta v_t^2 + h(s)$. The optimal braking force, denoted by $u_b^*$ is:

$$u_b^* = \begin{cases} 0 & \mu/v < \gamma \\ \ddot{u}_b & \mu/v = \gamma \\ 0 & \mu/v > \gamma \end{cases}$$ \hspace{1cm} (15)

In other words there is no singular interval during braking: For a singular interval to exist during braking, the condition $\frac{\mu}{v} = \gamma$ must be valid for a position interval rather than just at one point. Equation (13) indicates that during a braking singular interval the velocity has to be a constant. But we know that during braking the velocity cannot remain constant, hence there is no singular interval during a braking phase.

In summary Eq. (11) states that to minimize “wheel-to-distance” energy expenditure, the vehicle should decelerate or accelerate, as quickly as possible, to the constant speed of $v_{\text{sing}}$ and maintain that speed till close to destination. Optimal deceleration strategy starts by coasting but could end with a period of maximal braking even in absence of regeneration ($\gamma = 1$). With ideal regenerative brakes ($\gamma = 0$) the optimal strategy does not include a coasting phase. Values of $v_{\text{sing}}$ and $\lambda$ will be smaller for longer trip times $t_f$; its value can be obtained after solving the two-point boundary value problem described by (5) and (10).

ACKNOWLEDGEMENT

The first author was a scientific visitor at IFP Energies Nouvelles, Rueil-Malmaison, France for the duration of this collaborative work and thankfully acknowledges the support and sponsorship provided by IFPEN. The authors thank, Dr. Jihun Han, for his suggestions on the organization of the paper.

REFERENCES

Ardalan Vahidi is a Professor with the Department of Mechanical Engineering, Clemson University, Clemson, South Carolina. He received the Ph.D. degree in mechanical engineering from the University of Michigan, Ann Arbor, in 2005, the M.Sc. degree in transportation safety from George Washington University, Washington, DC, in 2002, and B.S. and M.Sc. degrees in civil engineering from Sharif University, Tehran, Iran, in 1996 and 1998, respectively. He has been a visiting scholar at the University of California, Berkeley and a visiting researcher at the BMW Group Technology Office USA in 2012-2013 and a scientific visitor at IFP Energies Nouvelles, France in 2017. His current research interests include control of vehicular and energy systems, and connected and automated vehicle technologies.

Antonio Sciarretta is an expert researcher with IFP Energies Nouvelles, Rueil Malmaison, France, since 2006. He received a M.Sc. (Mech. Eng.) degree in 1995, and a Doctorate degree (Thermal machines) in 1999, both from the University of L’Aquila, Italy. He earned a Habilitation (Control Eng.) in 2009 from the Grenoble Institute of Technology, France. Before joining IFPEN he has hold various teaching and research positions at the University of L’Aquila and at the ETH Zurich. From 2009 to 2016 he has hold the Tuck foundation Chair on Hybrid vehicles and energy management at IFP School. He has actively contributed to the development of hybrid-vehicle activities at IFPEN and he is currently managing research projects on the control and optimization for connected and automated vehicles. He has coauthored the Springer book Vehicle Propulsion Systems (three editions) and contributes to the scientific and professional community as a journal associate editor, conference organizer, and project evaluator.
